

Manipulation of Pose Distributions

Mark Moll, *Carnegie Mellon University, Pittsburgh, PA 15213*

Michael A. Erdmann, *Carnegie Mellon University, Pittsburgh, PA 15213*

Abstract

For assembly tasks parts often have to be oriented before they can be put in an assembly. The results presented in this paper are a component of the automated design of parts orienting devices. The focus is on orienting parts with minimal sensing and manipulation. We present a new approach to parts orienting through the manipulation of pose distributions. Through dynamic simulation we can determine the pose distribution for an object being dropped from an arbitrary height on an arbitrary surface. By varying the drop height and the shape of the support surface we can find the initial conditions that will result in a pose distribution with minimal entropy. We are trying to uniquely orient a part with high probability just by varying the initial conditions. We will derive a condition on the pose and velocity of an object in contact with a sloped surface that will allow us to quickly determine the final resting configuration of the object. This condition can then be used to quickly compute the pose distribution. We also present simulation and experimental results that show how dynamic simulation can be used to find optimal shapes and drop heights for a given part.

1 Introduction

In our research we are trying to develop strategies to orient three-dimensional parts with minimal sensing and manipulation. That is, we would like to bring a part from an unknown position and orientation to a known orientation (but possibly unknown position) with minimal means. In general, it is not possible to orient a part completely without sensors, but it is sufficient if a particular orienting strategy can bring a part into one particular orientation with high probability. The sensing is then reduced to a binary decision: a sensor only has to detect whether the part is in the right orientation or not. If not, the part is fed back

to the parts orienting device. Assuming the orienting strategy succeeds with high probability, on average it takes just a few tries to orient the part. An alternative view of this type of manipulation is to consider it as manipulation of the pose distribution. The goal then is to find the pose distribution with minimal entropy, thereby maximally reducing uncertainty.

1.1 Example

In this paper we will discuss the use of dynamic simulation for the design of support surfaces that reduce the uncertainty of a part's resting configuration. As the support surface is changed, the probability distribution function (pdf) of resting configurations will change as well. The pdf will also vary with the initial drop position above the surface. The following figure and paragraph illustrate the basic idea:

Figure 1: A part with an initially unknown orientation is dropped on a surface.

A part with an initially unknown orientation is released from a certain height and relative horizontal position with respect to the bowl. The only forces acting on the part are gravity and friction. We assume the bowl doesn't move. We can compute the final resting configuration for all possible initial orientations. This will give us the pdf of stable poses. The goal is to find the drop height, relative position and bowl shape that will maximally reduce uncertainty. In this paper we assume for simplicity that the initially unknown orientation is uniformly random, but our approach also works for different prior distributions.

	Stable Poses						Entropy
							
quasistatic approximation	0.20	0.13	0.16	0.21	0.14	0.16	1.78
dynamic, flat surface, drop height is $h = 0$	0.18	0.16	0.14	0.34	0.05	0.13	1.66
dynamic, bowl shape is $y = 0.24x^2$, $h = 0.28$, initial hor. pos. $x_0 = -0.41$	0.24	0.03	0.03	0.50	0.08	0.15	1.35

Table 1: Probability distribution function of stable poses for two surfaces. The initial velocity is zero and the initial rotation is uniformly random.

Table 1 shows three different pose distributions. Each stable pose corresponds to a set of contact points (marked by the black dots in the table). For an arbitrarily curved support surface the stable poses do not necessarily correspond to edges of the convex hull of the part. We therefore define a stable pose as a set of contact points. This means that any two poses with the same set of contact points are considered to be the same as far as the pose distribution is concerned. In our example the support surface is a parabola $y = ax^2$ with parameter a . Other parameters are the drop height, h , and the initial horizontal position of the drop location, x_0 . We limit the surface to parabolas for illustrative purposes only; in general we would use a larger class of possible shapes (see section 4.1).

The first row in the table shows the pdf assuming quasistatic dynamics. In this case the surface is flat and the part is released in contact with the surface. The second row shows how the pdf changes if we model the dynamics. The initial conditions are the same as for the quasistatic case, yet the pdf is significantly different. The third row shows the pdf for the optimized values for a , h and x_0 .

The objective function over which we optimize is the entropy of the pose distribution. If p_1, \dots, p_n are the probabilities of the n stable poses, then the entropy is $-\sum_{i=1}^n p_i \log p_i$. This function has two properties that make it a good objective function: it reaches its global minimum whenever one of the p_i is 1, and its maximum for a uniform distribution. By searching the parameter space we can find the a , h and x_0 that minimize the entropy. In the third row of the table the pose distribution is shown with minimal entropy¹. The table makes it clear that even with a very simple surface we can

¹This is a local minimum found with simulated annealing and might not be the global minimum.

reduce the uncertainty greatly by taking advantage of the dynamics.

1.2 Outline

In section 3 we will explain the notion of capture regions and introduce an extension and relaxation of this notion in the form of so-called quasi-capture regions. These quasi-capture regions allow for fast computation of pose distributions. In section 4 we will present our simulation and experimental results. Finally, in section 5 we will discuss the results presented in this paper. But first we will give an overview of related work in the next section.

2 Related Work

2.1 Parts Feeding and Orienting

One of the most comprehensive works on the design of parts feeding and assembly design is [12], which describes vibratory bowls as well as non-vibratory parts feeders in detail. The APOS parts feeding system is described by Hitakawa [26]. Berretty et al. [6] present an algorithm for designing a particular class of gates in vibratory bowls. Berkowitz and Canny [4, 5] use dynamic simulation to design a sequence of gates for a vibratory bowl. The dynamics are simulated with Mirtich’s impulse-based dynamic simulator, *Impulse* [35]. Christiansen et al. [16] use genetic algorithms to design a near-optimal sequence of gates for a given part. Optimality is defined in terms of throughput. Here, the behavior of each gate is assumed to be known. So, in a sense [16] is complementary to [5]: the latter focuses on modeling the behavior of gates, the former finds an optimal sequence of gates given their behavior. Akella et al. [1] introduced a technique for orienting planar parts on a conveyor belt with a one degree-of-freedom

(DOF) manipulator. Lynch [32] extended this idea to 3D parts on a conveyor belt with a two DOF manipulator. Wiegley et al. [43] presented a complete algorithm for designing passive fences to orient parts. Here, the initial orientation is unknown.

Goldberg [22] showed that it is possible to orient polygonal parts with a frictionless parallel-jaw gripper without sensors. Marigo et al. [34] showed how to orient and position a polyhedral part by rolling it between the two hands of a parallel-jaw gripper. Grossman and Blasgen [25] developed a manipulator with a tactile sensor to orient parts in a tray. Erdmann and Mason [18] developed a tray-tilting *sensorless* manipulator that can orient planar parts in the presence of friction. If it isn't possible to bring a part into a unique orientation, the planner would try to minimize the number of final orientations. In [19] it is shown how (with some simplifying assumptions) three-dimensional parts can be oriented using a tray-tilting manipulator. Zumel [45] used a variation of the tray tilting idea to orient planar parts with a pair of moveable palms.

In recent years a lot of work has been done on programmable force fields to orient parts [9, 10, 28]. The idea is that a kind of force ‘field’ (implemented using e.g. MEMS actuator arrays) can be used to push the part in a certain orientation. Kavraki [28] presented a vector field that induced two stable configurations for most parts. Böhringer et al. [9, 10] used Goldberg’s algorithm [22] to define a sequence of ‘squeeze fields’ to orient a part. They also gave an example how programmable vector fields can be used to simultaneously sort different parts and orient them.

2.2 Stable Poses

To compute the stable poses of an object quasistatic dynamics is often assumed. Furthermore, usually it is assumed that the part is in contact with a flat surface and is initially at rest. Boothroyd et al. [11] were among the first to analyze this problem. An $O(n^2)$ algorithm for n -sided polyhedrons, based on Boothroyd et al.’s ideas, was implemented by Wiegley et al. [44]. Goldberg et al. [21] improve this method by approximating some of the dynamic effects. Kriegman [30] introduced the notion of a *capture region*: a region in configuration space such that any initial configuration in that region will converge to one final configuration. Note that his work doesn’t assume quasistatic dynamics; as long as the part is initially at rest and in con-

tact, and the dynamics in the system are dissipative, the capture regions will be correct. The capture regions will in general not cover the entire configuration space.

2.3 Collision and Contact Analysis

For rigid body collisions several models have been proposed. Many of these models are either too restrictive (e.g., Routh’s model [39] constrains the collision impulse too much) or allow physically impossible collisions (e.g., Whittaker’s model [42] can predict arbitrarily high increases of system kinetic energy). Recently, Chatterjee and Ruina [15] proposed a new collision rule, which avoids many of these problems. Chatterjee introduced a new collision parameter (besides the coefficients of friction and restitution): the coefficient of *tangential* restitution. With this extra parameter a large part of allowable collision impulses can be accounted for, and at the same time this collision rule restricts the predicted collision impulse to the allowable part of impulse space. This is the collision rule we will use (see [36] for details).

Instead of having algebraic laws, one could also try to model object interactions during impact. This approach is taken, for instance, by Bhatt and Koechling [7, 8], who modeled impacts as a flow problem. While this might lead to more accurate predictions, it is obviously computationally more expensive. Also, in order to get a good approximation of the pdf of resting configurations, this level of accuracy might not be required. On the other hand, it is also possible to combine the effects of multiple collisions that happen almost instantaneously. Goyal et al. [23, 24] studied these “clattering” motions and derived the equations of motion.

Given a collision model and the equations of motion, one can simulate the motion of a part. In cases where there are a large number of collisions or with contact modes that change frequently one can simulate the dynamics using so-called impulse-based simulation [35]. However, there are limits to what systems one can simulate. Under certain conditions the dynamics become chaotic [13, 20, 29]. We are mostly interested in systems that are *not* chaotic, but where the dynamics can not be modeled with a quasistatic approximation. In section 4.1 a number of ‘chaos plots’ are shown that are very similar to the one in [29].

2.4 Shape Design

The shape of an object and its environment imposes constraints on the possible motions of an object. Caine [14] presents a method to visualize these motion constraints, which can be useful in the design phase of both part and manipulator. In [31] the mechanics of entrapment are analyzed. That is, Krishnasamy discusses conditions for a part to “get trapped” and “stay trapped” in an extrusion in the context of the APOS parts feeder. Sanderson [40] presents a method to characterize the uncertainty in position and orientation of a part in an assembly system. This method takes into account the shape of both part and assembly system. In [33] the optimal manipulator shape and motion are determined for a particular part. The problem here was not to orient the part, but to perform a certain juggler’s skill (the “butterfly”). With a suitable parametrization of the shape and motion of the manipulator, a solution was found for a disk-shaped part that satisfied their motion constraints. Although the analysis focuses just on the juggling task, it shows that one can simulate and optimize dynamic manipulation tasks using a suitable parametrization of manipulator (or surface) shape and motion.

3 Analytic Results

3.1 Quasi-Capture Intuition

In our efforts to analyze pose distributions in a dynamic environment, we have been working on a generalization of so-called ‘capture regions’ [30] that we have termed *quasi-capture regions*. Specifically, for a part in contact with a sloped surface, we would like to determine whether it is captured, i.e., whether the part will converge to the closest stable pose. For simplicity, let the surface be a tilted plane.

Definition 1 Let a *pose* be defined as a point in configuration space such that the part is contact with the surface.

We assume that friction is sufficiently high so that a part cannot slide for an infinite amount of time. In general capture depends on the whole surface and everything that happens after the current state, but the friction assumption and our definition of pose allow us to define quasi-capture (in section 3.2) of the part in

terms of local state. The closest stable pose can be defined as follows:

Definition 2 We define a *stable pose* to be a pose such that there is force balance when only gravity and contact forces are acting on the part. The *closest stable pose* is the stable pose found by following the gradient of the potential energy function (using e.g. gradient descent) from the current pose.

We can now define quasi-capture regions:

Definition 3 A *quasi-capture region* is the largest possible region in configuration phase space such that (a) all configurations in this region have the same closest stable pose and (b) no configuration in a quasi-capture region has enough (kinetic and potential) energy to leave this region either with a rolling motion or one collision-free motion.

Ideally these quasi-capture regions would induce a partition of configuration phase space, so that for each point in phase space we would immediately know what its final resting configuration is. Of course, this is not the case in general, since with a sufficiently large velocity an object can reach any stable pose. But if we restrict the velocity to be small to begin with, then we are able to quickly determine the pose distribution. It has been our experience that without the use of quasi-capture regions a lot of computation time is spent on the final part/surface interactions (e.g. clattering motions) before the part reaches a stable pose. In other words, *with our analytic results it is possible to avoid computing a potentially large number of collisions*.

In our analysis we have focused on the two dimensional case. To illustrate the notion of capture, we will start with another example. Consider a rod of length l with center of mass at distance R from each vertex. One can visualize this rod as a disk with radius R and uniform mass, but with contact points only at the ends of the rod (see figure 2).

Note that the endpoints of the rod are numbered. We will refer to these endpoints later. Let the ‘side’ of the rod where the center of mass is above the rod be the *high energy side*, and the other side be the *low energy side*. We can then define that the rod is ‘on’ the high energy side if and only if the center of mass is

Figure 2: A rod with an off-center center of mass.

between and above the endpoints of the rod. Suppose the rod is in contact with a flat, horizontal surface. For the rod to make a transition from one side to the other, it will have to rotate, either by rolling or by bouncing. At some point during the transition the center of mass will pass over one of the endpoints of the rod. Its potential energy at that point will always be greater than or equal to the potential energy at the start of the transition. Hence, to make that transition the rod has to have a minimum amount of kinetic energy. This can be written more formally as

$$\frac{1}{2}m\|\mathbf{v}\|^2 > -mg\Delta h. \quad (1)$$

Figure 3 illustrates this requirement.

Figure 3: Capture condition for a rod.

For a polygonal object in contact with a surface with constant slope we will derive in section 3.2 a lower bound on the norm of the velocity such that for all velocities below that bound the part will be quasi-captured. As we vary the position of the center of mass with respect to the rod endpoints, the slope of the support surface and the drop height, the bound for the capture velocity will change. This bound will also depend on the relative orientation of the contact point with respect to the center of mass.

For a sloped surface the capture condition is not as simple as for the horizontal surface. By bouncing and rolling down the slope, the rod can increase its kinetic energy. We have derived an upper bound on how far the rod can bounce. This gives an upper bound on the increase in kinetic energy. So the quasi-capture condition can now be stated as: the current kinetic energy

plus the maximum gain in kinetic energy has to be less than the energy required to rotate to the other side. To guarantee that the rod is indeed captured, we have to make sure that the maximum gain in kinetic energy is less than the decrease in kinetic energy due to a collision. There are some additional complicating factors. For instance, a change in orientation can increase the kinetic energy, but to rotate to the other side the rod has to rotate back, undoing the gain in kinetic energy.

3.2 Quasi-Capture Velocity

What we will prove is a sufficient condition on the pose and velocity of the rod such that it is quasi-captured. The condition will be of the following form: if the current kinetic energy plus the maximal increase in kinetic energy is less than some bound, the rod is quasi-captured. This bound depends on the current orientation, the current velocity, the slope of the surface and the geometry of the rod. Because of the way we have set up our generalized coordinates (see [36] for details), the kinetic energy is $\frac{1}{2}m\|\mathbf{v}\|^2$. In other words, the mass is just a constant scalar. Without loss of generality we can assume $m = 2$. That way the kinetic energy is simply $\|\mathbf{v}\|^2$. We will write v for $\|\mathbf{v}\|$.

Theorem 4 *The rod with a velocity vector of length v and in contact with the surface is in a quasi-capture region if the following condition holds:*

$$v^2 + \frac{2v \cos \xi \sin \phi}{\cos^2 \phi} (v \sin(\xi + \phi) + \sqrt{v^2 \sin^2(\xi + \phi) - 2gd_n \cos \phi}) - 2g\left(\frac{d_n}{\cos \phi} + R\varepsilon\right) \leq -2gR(1 + \cos(\frac{\alpha}{2} + \phi)),$$

where ξ is the direction of the velocity vector that will result in the largest increase of kinetic energy, θ is the relative orientation of the contact point, $d_n = R(\cos \frac{\alpha}{2} - \sin(\theta + \phi))$ and $\varepsilon = \cos(\frac{\alpha}{2} + \phi) - \frac{\cos(\alpha/2)}{\cos \phi} + \max(\tan \phi, 2 \sin \frac{\alpha}{2} \sin \phi)$.

Proof: See appendix A. \square

Note that for $\phi = 0$ this bound reduces to $v^2 \leq -2gR(1 + \sin \theta)$. In other words, this bound is as tight as possible when the surface is horizontal.

One can compute ξ numerically, but the appendix also gives a good analytic approximation. The theorem above gives a sufficient condition on the velocity and pose of the rod such that it cannot rotate to the other side during one bounce. But suppose there is a

Figure 4: *Quasi-capture velocity as a function of the slope of the surface and the orientation of the rod*

sequence of bounces, each of them increasing the kinetic energy. It is possible that the rod satisfies the quasi-capture condition, but is still able to rotate to the other side in more than one bounce. Thus, the theorem by itself is not enough to guarantee that the rod will converge to its closest stable orientation. In the analysis above we have ignored the dissipation of kinetic energy during collisions. If in the case the capture condition is true the dissipation of kinetic energy is larger than the increase due to the bounce, the rod will indeed be captured after an arbitrary number of bounces. To make sure this is the case the coefficients of restitution can not be too large.

In figure 4 the quasi-capture velocity is plotted as a function of the slope of the surface and the orientation of the rod. The slope ranges from 0 to $\frac{\pi}{2}$ and the orientation ranges from 0 to 2π . Note that the orientation of the rod is not the same as the relative orientation of the contact point. However, for each combination of ϕ and θ the relative orientation of the contact point can be easily computed. The other relevant parameter values for this plot are: $R = 1m$, $g = -9.81m/s^2$ and $\alpha = \frac{\pi}{2}$. The little bump in the middle corresponds to the rod being captured on the high-energy side. The bigger bumps on the left and right correspond to being captured on the low-energy side.

4 Simulation and Experimental Results

4.1 Dynamic Simulation

To numerically compute the pose distribution of parts, we have written two dynamic simulators. One is based on David Baraff’s Coriolis simulator [2, 3], which can simulate the motions of polyhedral rigid bodies. Coriolis takes care of the physical modelling. Our simulator then computes pose distributions for different (parametrized) support surfaces and different initial conditions.

Our simulator uses simulated annealing to optimize over the surface parameters and drop location with respect to the surface. The objective function is to minimize the entropy of the pose distribution. Initially the sampling of orientations of the object is rather coarse, so that the resulting pose distribution is not very accurate. But as the simulator is searching, the simulated annealing algorithm is restarted with an increased sample size and the best current solution as initial guess. This way we can quickly determine the potentially most interesting parameter values and refine them later. Our implementation is based on the one given in [37, pp. 444–455].

Surfaces are parametrized using wavelets [41, 17]. Wavelet transforms are similar to the fast Fourier transform, but unlike the fast Fourier transform basis functions (sines and cosines) wavelet basis functions are localized in space. This localization gives us greater flexibility in modeling different surfaces compared with the fast Fourier transform or, say, polynomials. There are many classes of wavelet basis functions. We are using the Daubechies wavelet filters [17] and in particular the implementation as given in [37, pp. 591–606]. To reduce an arbitrary surface to a small number of coefficients we first discretize the function describing the surface. We then perform a wavelet transform and keep the largest components (in magnitude) in the transform to represent the surface. When we minimize the entropy, we optimize over these components. We can either keep the smaller components of our initial wavelet transform around or set them to zero.

Development of a second simulator was started, because Coriolis had some limitations. In particular, the collision model could not be changed and we wanted to experiment with Chatterjee’s collision model [15]. The second simulator also allowed us to optimize for our

specific dynamics model. In our model there is only one moving object, and the only forces acting on it are gravity and friction. Currently, the simulator only handles two-dimensional objects, but in the future it might be extended to handle three dimensions as well. It uses the analytic results from the previous section to stop simulating the motion of the part once it is captured.

Using the simulator we can compute the quasi-capture regions for the rod. Figures 5(a)–(c) show the quasi-capture regions for the low energy side after one, three and five bounces. The dark areas correspond to initial orientations and initial velocities that result in the rod being quasi-captured. The zero orientation is defined as the orientation where endpoint 1 is to the right of the center of mass. The triangles below the x-axes show the pose of the rod corresponding to the orientation at that point of the x-axes.

Let the optimal drop height be defined as the drop height that maximizes the probability of ending up on the low energy side. Then dropping the rod with uniformly random initial orientation from the optimal drop height will reduce uncertainty about its orientation maximally (unless there exists a drop height that will result in an even higher probability for the high energy side). In figures 5(a)–(c) the drop height that results in the maximum probability of ending up on the low energy side is marked by a horizontal line. After each successive bounce this drop height is likely to be a better approximation of the optimal drop height. In figure 5(d) the approximate optimal drop height and lower bound on the probability of ending up on the low-energy side after one through five bounces is shown. One thing to note is that both the optimal drop height and the lower bound on the probability of ending up on low-energy side rapidly converge. This seems to suggest that after only a small number of bounces we could make a reasonable estimate of the optimal drop height and uncertainty reduction. Further study is needed to find out if this is true in general.

4.2 2D Results

To verify the simulations we also performed some experiments. Our experimental setup was as follows. We used an air table to effectively create a two-dimensional world. By varying the slope of the air table we can vary the gravity. At the bottom of the slope is the surface on which the object will be dropped. The angle ϕ of

Table 2: Simulation and experimental results for the rod. Shown are the probabilities of ending up on the low-energy side for different values for g , h and ϕ . The drop height is measured from the center of the disk to the surface.

the surface in the plane defined by the air table can, of course, be varied.

The rod of the previous section has been implemented as a plastic disk with two metal pins sticking out from the top at an equal distance from the center of the disk. When released from the top of the air table the disk can slide under the surface and will only collide at the pins. Experimentally we determined the pose distribution of the rod for different values for g , h and ϕ by determining the final stable pose for 72 equally spaced initial orientations. Our simulation and experimental results of some tests have been summarized in table 2. The rows marked with an asterisk have been used to estimate the moment of inertia of the rod and the coefficients of friction and restitution. The estimated values for these parameters are: $e = 0.404$, $e_t = -0.136$, $\rho = 0.0376$ and $\mu = 4.71$. Note that for a low drop height and a horizontal surface the pdf is equal to a quasistatic approximation, as one would expect. More surprisingly, we see that the probability of ending up on the low-energy side can be changed to approximately 0.95 by setting g , h and ϕ to appropriate values. In other words, we can reduce the uncertainty almost completely.

One can identify several error sources for the differences between the simulation and experimental results. First, there are measurement errors in the experiments:

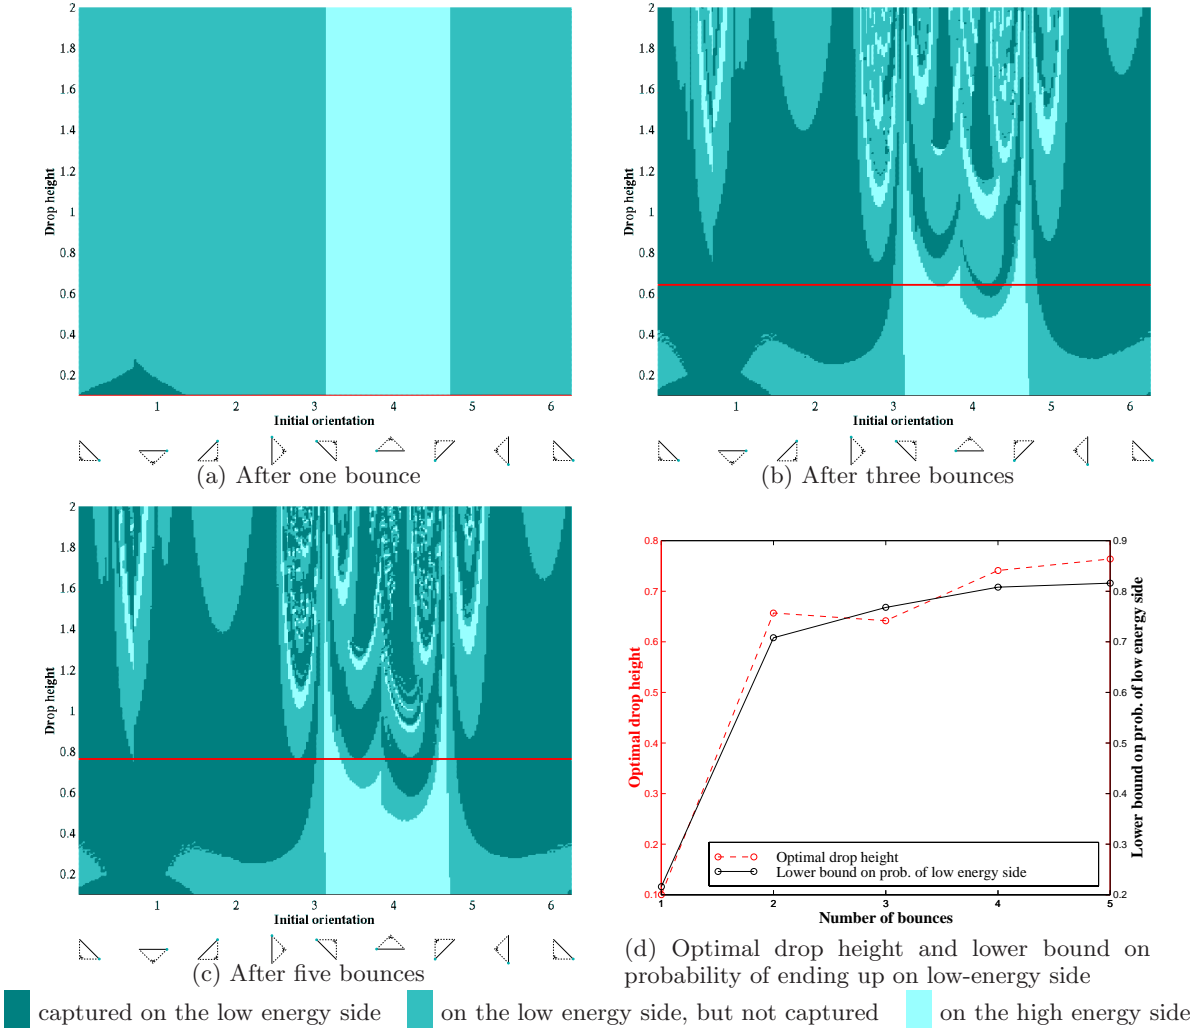

Figure 5: *Quasi-capture regions for the low energy side of the rod on a 7° slope.* The rod parameters are $\alpha = \pi/2$, $R = 0.05m$, gravity, g , equals $-1.20m/s^2$, the coefficient of friction, μ , is 5 and the restitution parameters are: $e = 0.1$, $e_t = -0.2$.

in some cases slight changes in the initial conditions will change the side on which the rod will end up. Second, since the simulations are run with finite precision, it is possible that numerical errors affect the results. Finally, the physical model is not perfect. In particular, the rigid body assumption is just false. The surface on which the rod lands is coated with a thin layer of foam to create a high-damping, rough surface. This is done to prevent the rod from colliding with the sides of the air table.

4.3 3D Results

We have not generalized our analytic results to three dimensions yet, but we can still use our optimization technique to find a good surface and drop height for a given object. For the dynamic simulation we rely now on Baraff's Coriolis simulator. Figure 6(a) shows an orange insulator cap² at rest on flat, horizontal surface. The contact points are marked by the little spheres. In figure 6(b) the bowl resulting from the simulated

²This object has been used before as an example in [21, 30, 38].

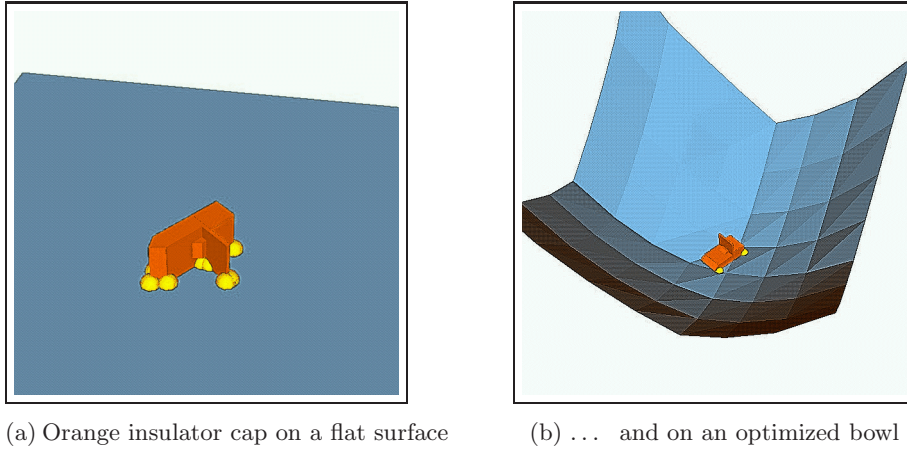

Figure 6: Result of optimizing a surface for the orange insulator cap.

Figure 7: Entropy as a function of the two principal axes of the searched five-dimensional parameter space.

annealing search process is shown. The initial shape is a paraboloid: $f(x, y) = (x^2 + y^2)/20$. This shape is reduced to a triangulation of a 8×8 regular grid. The part is always released on the left-hand side of the bowl.

We optimized over the four largest wavelet coefficients of the initial shape and the drop height. The search for the optimal bowl and drop height is visualized in figure 7. The five-dimensional parameter space is projected onto a two-dimensional space using Principal Component Analysis [27]. Each point corresponds to a bowl shape evaluation, i.e., for each point a pose distribution is computed. The size of each point is proportional to the sample size used to determine the pose

distribution. Computing a pose distribution by taking 600 samples takes about 40 minutes on a 500 MHz Pentium III. The surface in figure 7 is a cubic interpolation between the points. The dark areas correspond to areas of low entropy. Notice that most of the points are in or near a dark area.

Table 3 compares the simulation results with experimental data from [21]. The format is the same as in table 1, except that the stable poses are now written as vectors. These vectors are the outward pointing normals (w.r.t. the center of mass) of the planes passing through the contact points. That way, a face with many vertices in contact with the surface will always be represented by the same vector, no matter which subset of the vertices is actually in contact. In the experimental setup of [21] the part was dropped from one conveyer belt onto another. The initial drop height was 12.0 cm. In the experiments the part had an initial horizontal velocity of 5.0 cm/s. The second row corresponds to computing the pose distribution when the part is dropped from 12.0 cm (but with initial velocity set to 0). The third row corresponds to a local minimum returned by the simulated annealing algorithm.

5 Discussion

We have shown a sufficient condition on the position and velocity of the simplest possible ‘interesting’ shape (i.e., the rod) that guarantees convergence to the nearest stable pose under some assumptions. This condition gives rise to regions in configuration phase-space,

	Stable Poses						Entropy
	$(-1, 0, 0)$	$(0, -1, 0)$	$(0, 1, 0)$	$(.8, 0, .6)$	$(.7, 0, -.7)$	$(0, 0, -1)$

Table 3: Probability distribution function of stable poses for two surfaces. The initial velocity is zero and the initial rotation is uniformly random. The experimental data is taken from [21]. There, $(0, -1, 0)$ and $(0, 1, 0)$ are counted as one pose.

where each point within such a region will converge to the same stable pose. We have coined the term quasi-capture regions for these regions, since they are very similar to Kriegman’s notion of capture regions. In simulations quasi-capture always seems to imply capture, but further research is needed to prove this claim.

The quasi-capture regions also apply to general polygonal shapes. However, we can no longer use the symmetry of the rod. So the quasi-capture expressions for general polygonal shapes become more complex. On the other hand, we might be able to orient planar parts by using a setup similar to the one described in section 4 and attaching two pins to the top of the part. Generalizing the quasi-capture regions to three dimensions is non-trivial and is an interesting direction for future research.

The simulation and experimental results show that the simulator is not 100% accurate, but that it is a useful tool for determining the most promising initial conditions for uncertainty reduction. In other words, the optimum predicted by the simulator will probably be near-optimal in the experiments. We can then experimentally search for the true optimum.

Another area where quasi-capture regions may be applied is in computer animation. Before a part comes to rest, there are many interactions between the part and the support surface. It turns out that these interactions are computationally very expensive. With our capture regions we can eliminate the last ‘clattering’ motions of the part, since we can predict what the final pose will be. For applications where fast animation is more important than physical accuracy, a pre-computed motion can be substituted for the actual motion.

With future research we hope to improve the constraints on the quasi-capture velocity by taking into account more information, such as the direction of the velocity vector. If improving the quasi-capture bounds

is impossible, it might be possible to get better approximations for pose distributions. As noted in section 4.1 it is possible to get a good estimate of the maximal uncertainty reduction after only a small number of bounces of the rod. So another interesting line of research would be to find out how accurate these approximations are in general. We are also planning to do more experiments to verify our current and future analytic results.

Appendix A: Proof of Theorem 4

Definition 5 Let a bounce be defined as the flight path between two impacts.

The closest distance between the rod and the slope during one bounce can be described by

$$d(t) = \frac{1}{2}g(\cos \phi)t^2 + (v_y \cos \phi + v_x \sin \phi)t - d_{\theta(t)}, \quad (2)$$

where v_x and v_y are the translational components of the velocity and $d_{\theta(t)}$ is a component that depends on the orientation. Let the rod be in contact at $t = 0$. Then $d(0) = 0$ (and therefore $d_{\theta(0)} = 0$). Let \hat{t} be the smallest positive solution to $d(t) = 0$. The change in height is then $\Delta h = \frac{1}{2}g\hat{t}^2 + v_y\hat{t}$, so that the change in v^2 is $\Delta v^2 = 2g\Delta h = g^2\hat{t}^2 + 2v_yg\hat{t}$. To find the maximum Δv^2 for all velocity vectors of length v we can parametrize the translational velocity as $v_x = v \cos \xi$ and $v_y = v \sin \xi$, and maximize over ξ . This ignores the rotational component of the velocity, but the following lemma shows that for a certain value of $d_{\theta(\hat{t})}$ the resulting solution for Δv^2 is an upper bound for the true maximal increase of v^2 .

Definition 6 Let the *ideal orientation* be defined as the orientation where the rod is parallel to the surface and the center of mass is below the rod.

Lemma 7 *We can always increase the rod's kinetic energy after a bounce by allowing it to rotate around the center of mass 'for free' (i.e., without using energy) to the ideal orientation (ignoring penetrations of the surface) and then letting it continue to fall while maintaining this orientation. However, if the rod is already in the ideal orientation after the bounce, its kinetic energy cannot be increased.*

Proof: One can easily verify that rotating around the center of mass to the ideal orientation of the bounce

(a) Change in distance between the center of mass and the surface in poses with the initial and ideal orientation

(b) Trajectory of the center of mass during a bounce

Figure 8: Increase in kinetic energy when rotating to the ideal orientation

maximizes distance between the rod and the surface. This distance will always be greater than or equal to 0. If we allow the rod to continue to fall until it hits the surface, its kinetic energy will increase. \square

From this lemma it follows that by assuming the rod rotates ‘for free’ to the ideal orientation the increase in kinetic energy due to one bounce is an upper bound on the true increase of kinetic energy. With this lemma computing the next contact point is a lot easier. Let θ be the relative orientation of the contact point at $t = 0$. $\theta = 0$ corresponds to the contact point being to the right of the center of mass. The signed distance from the center of mass to the surface at $t = 0$ is then $-R \sin(\theta + \phi)$, as shown in figure 8(a). One can easily verify that in the ideal orientation the relative orientation of endpoint 1 is $\frac{\pi}{2} - \frac{\alpha}{2} - \phi$. Let $\hat{\theta}$ be equal to this relative orientation. In the pose where the rod is in contact with the surface and has the ideal orientation the signed distance from the center of mass to the surface is $-R \sin(\hat{\theta} + \phi) = -R \cos \frac{\alpha}{2}$. So in total the center of mass travels at most a distance $R(\cos \frac{\alpha}{2} - \sin(\theta + \phi))$ in the direction normal to the surface during one bounce. Let d_n be equal to this distance. To solve for the time of impact we can treat the rod as a point mass centered at the center of mass and replace $d_{\theta(\hat{t})}$ in equation 2 with $-d_n$. Equation 2 is then simply a paraboloid in t . The distance function now measures the distance between the center of mass and the dotted line parallel to the surface shown in figure 8(b). This approach is not limited to the case where our new orientation is the ideal orientation. Suppose an oracle would tell us that the new orientation is $\tilde{\theta}$. Then we can solve for the time of

impact by substituting $R(\sin(\tilde{\theta} + \phi) - \sin(\theta + \phi))$ for $d_{\theta(\hat{t})}$ in equation 2.

The following lemma gives a bound on the velocity needed to roll to the other side.

Lemma 8 *If the rod is in rolling contact, then to be able to roll to the other side the following condition has to hold: $v^2 > -2gR(1 + \sin \theta + (\text{sign}(\cos \theta) - 1) \sin \frac{\alpha}{2} \sin \phi)$. We assume $0 \leq \phi < \frac{\pi}{2}$.*

Proof: We can distinguish several cases: endpoint 1 of the rod or endpoint 2 can be in contact with the slope, and the rod can be on the low or high energy side. We will prove the case where endpoint 1 is in contact and the rod is on the high energy side. The proof for the other cases is analogous. The case under consideration is shown in figure 9(a). To roll counterclockwise over to the left side, $v^2 > -2gh_1$. The distance h_1 is simply equal to $R(1 + \sin \theta)$. If the rod rolls clockwise over to two-point contact and continues to roll over endpoint 2, the rod gains kinetic energy because the second contact point is lower than the first contact point. This gain is proportional to h_2 .

One can easily verify that for two-point contact the relative orientations of contact points 1 and 2 are $\frac{3\pi}{2} - \frac{\alpha}{2} - \phi$ and $\frac{3\pi}{2} + \frac{\alpha}{2} - \phi$, respectively. The bound for rolling over endpoint 2 is therefore

$$\begin{aligned} v^2 &> -2g(h_3 - h_2) \\ &= -2gR(1 + \sin \theta - \cos(\frac{\alpha}{2} - \phi) + \cos(\frac{\alpha}{2} + \phi)) \\ &= -2gR(1 + \sin \theta - 2 \sin \frac{\alpha}{2} \sin \phi). \end{aligned}$$

If the center of mass is to the left of the contact point the last term will change sign. We can therefore com-

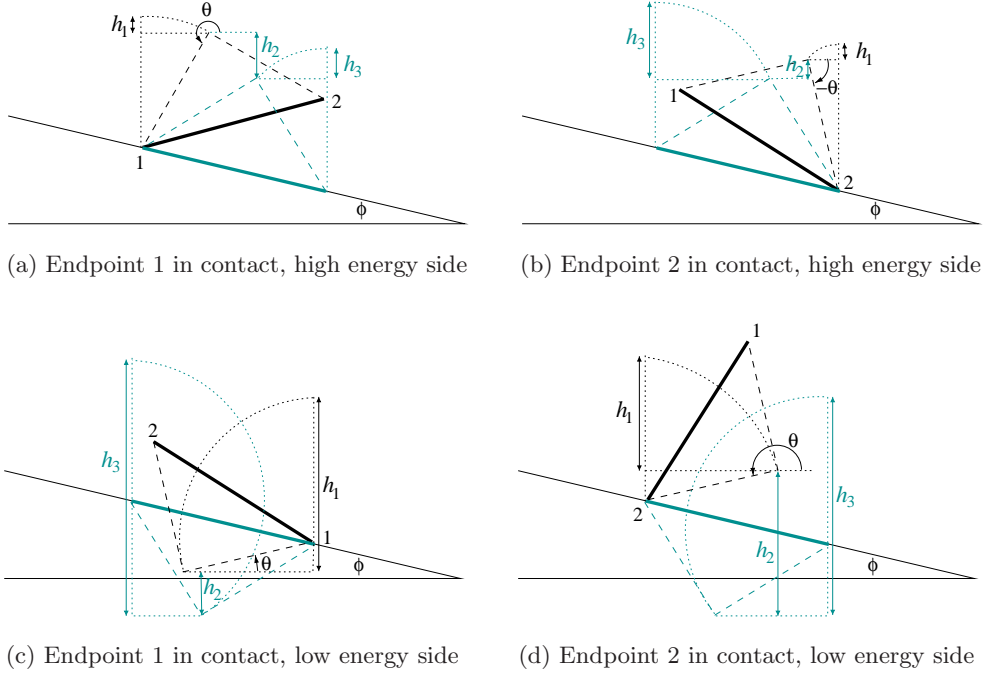

Figure 9: Capture condition for rotation

bine the two bounds (one for rotating clockwise, and for rotating counterclockwise) into this bound:

$$\begin{aligned}
 v^2 &> \min(-2gR(1 + \sin \theta), \\
 &\quad -2gR(1 + \sin \theta + 2 \operatorname{sign}(\cos \theta) \sin \frac{\alpha}{2} \sin \phi)) \\
 &= -2gR(1 + \sin \theta + (\operatorname{sign}(\cos \theta) - 1) \sin \frac{\alpha}{2} \sin \phi). \quad (3)
 \end{aligned}$$

□

Theorem 4 *The rod with a velocity vector of length v and in contact with the surface is in a quasi-capture region if the following condition holds:*

$$\begin{aligned}
 v^2 + \frac{2v \cos \xi \sin \phi}{\cos^2 \phi} (v \sin(\xi + \phi) + \sqrt{v^2 \sin^2(\xi + \phi) - 2gd_n \cos \phi}) \\
 - 2g\left(\frac{d_n}{\cos \phi} + R\varepsilon\right) \leq -2gR(1 + \cos(\frac{\alpha}{2} + \phi)),
 \end{aligned}$$

where ξ is the direction of the velocity vector that will result in the largest increase of kinetic energy, $d_n = R(\cos \frac{\alpha}{2} - \sin(\theta + \phi))$ and $\varepsilon = \cos(\frac{\alpha}{2} + \phi) - \frac{\cos(\alpha/2)}{\cos \phi} + \max(\tan \phi, 2 \sin \frac{\alpha}{2} \sin \phi)$.

Proof: The path of the center of mass during a bounce that increases the kinetic energy maximally is described by $\frac{1}{2}gt^2 \cos \phi + v(\sin \xi \cos \phi + \cos \xi \sin \phi)t + d_n =$

0. The smallest positive solution of this equation is

$$\begin{aligned}
 \hat{t} &= \frac{-v(\sin \xi \cos \phi + \cos \xi \sin \phi)}{g \cos \phi} \\
 &\quad - \frac{\sqrt{v^2(\sin \xi \cos \phi + \cos \xi \sin \phi)^2 - 2gd_n \cos \phi}}{g \cos \phi} \quad (4) \\
 &= \frac{-v \sin(\xi + \phi) - \sqrt{v^2 \sin^2(\xi + \phi) - 2gd_n \cos \phi}}{g \cos \phi}.
 \end{aligned}$$

The maximum change in v^2 is then bounded by

$$\begin{aligned}
 \Delta v^2 &= 2g\Delta h \leq 2g\left(\frac{1}{2}g\hat{t}^2 + v(\sin \xi)\hat{t}\right) \\
 &= \frac{2v \cos \xi \sin \phi}{\cos^2 \phi} (v \sin(\xi + \phi) \\
 &\quad + \sqrt{v^2 \sin^2(\xi + \phi) - 2gd_n \cos \phi}) - \frac{2gd_n}{\cos \phi}. \quad (5)
 \end{aligned}$$

After one bounce the orientation is assumed to be such that rod is parallel to the surface and the center of mass is below the rod, as this will result in the largest increase in kinetic energy according to lemma 1. This means that endpoint 1's relative orientation is equal to $\hat{\theta} = \frac{\pi}{2} - \frac{\alpha}{2} - \phi$. Substituting this value in equation 3 of lemma 2 gives $-2gR(1 + \sin \hat{\theta})$. In other words, if the kinetic energy after the bounce is less than $-2gR(1 + \sin \hat{\theta})$ and the rod is in the ideal orientation, the rod cannot roll to the other side.

We can combine the two bounds to obtain a sufficient condition to determine whether the rod can rotate to the other side *if its new orientation after one bounce is equal to the ideal orientation*. Unfortunately this condition does not imply a similar condition for the general case where the new orientation is not necessarily equal to the ideal orientation.

Consider the case $v = 0^+$. Substituting this value in equation 5 and expanding the definition of d_n shows that the maximum increase in kinetic energy is then

$$-\frac{2gd_n}{\cos\phi} = -\frac{2gR(\sin(\hat{\theta}+\phi)-\sin(\theta+\phi))}{\cos\phi}. \quad (6)$$

Therefore, when $v = 0^+$ and the relative orientation of the contact point after the bounce is equal to ideal orientation the quasi-capture constraint is

$$-2gR\frac{\sin(\hat{\theta}+\phi)-\sin(\theta+\phi)}{\cos\phi} \leq -2gR(1 + \sin\hat{\theta}). \quad (7)$$

That is, if an upper bound on the kinetic energy after one bounce is less than the energy needed to rotate to the other side, the rod will not be able to rotate to the other side. Now suppose the new orientation is *not* equal to the ideal orientation. Then the increase of kinetic energy will be less, but the energy required to roll to the other side will be less, too. Let $\hat{\theta}$ be the relative orientation of the contact point after the bounce. Equation 7 is of the form $f(\hat{\theta}) \leq g(\hat{\theta})$, where $f(\cdot)$ computes the kinetic energy after one bounce for a given new orientation and $g(\cdot)$ computes the energy needed to roll to the other side for a given orientation³. Unfortunately, this bound does not imply $\forall\hat{\theta}.f(\hat{\theta}) \leq g(\hat{\theta})$. From the ‘oracle argument’ on page 13 it follows that $f(\hat{\theta})$ is indeed an upper bound on the maximum increase of the kinetic energy. Substituting $\tilde{\theta}$ in lemma 2 shows that $g(\tilde{\theta})$ is a lower bound on the kinetic energy needed to roll to the other side. We would like to determine the smallest possible ε such that

$$f(\hat{\theta}) - 2gR\varepsilon \leq g(\hat{\theta}) \quad \Rightarrow \quad \forall\tilde{\theta}.f(\tilde{\theta}) \leq g(\tilde{\theta}).$$

It is not hard to see ε has to be equal to

$$\max_{\hat{\theta}}(g(\hat{\theta}) - g(\tilde{\theta}) - f(\hat{\theta}) + f(\tilde{\theta})) / (-2gR).$$

The difference between $f(\hat{\theta})$ and $f(\tilde{\theta})$ is

$$-2gR\frac{\sin(\hat{\theta}+\phi)-\sin(\tilde{\theta}+\phi)}{\cos\phi}.$$

³Analogous to expression 3, $g(\tilde{\theta})$ equals $-2gR\left(1 + \sin\tilde{\theta} + (\text{sign}(\cos\tilde{\theta}) - 1)\sin\frac{\alpha}{2}\sin\phi\right)$.

Similarly, the difference between $g(\hat{\theta})$ and $g(\tilde{\theta})$ is

$$-2gR\left(\sin\hat{\theta} - \sin\tilde{\theta} - (\text{sign}(\cos\tilde{\theta}) - 1)\sin\frac{\alpha}{2}\sin\phi\right).$$

The correction ε is therefore

$$\varepsilon = \max_{\hat{\theta}}(\sin\hat{\theta} - \sin\tilde{\theta} - (\text{sign}(\cos\tilde{\theta}) - 1)\sin\frac{\alpha}{2}\sin\phi - \frac{\sin(\hat{\theta}+\phi)-\sin(\tilde{\theta}+\phi)}{\cos\phi})$$

By differentiating the expression inside $\max(\cdot)$ with respect to $\tilde{\theta}$ we find that there is a local maximum at $\tilde{\theta} = 0$. Other local maxima occur when $\tilde{\theta}$ approaches $-\frac{\pi}{2}$ from below or $\frac{\pi}{2}$ from above. The correction ε therefore simplifies to

$$\begin{aligned} \varepsilon &= \max\left(\sin\hat{\theta} - \frac{\sin(\hat{\theta}+\phi)-\sin\phi}{\cos\phi}, \sin\hat{\theta} + 2\sin\frac{\alpha}{2}\sin\phi - \frac{\sin(\hat{\theta}+\phi)}{\cos\phi}\right) \\ &= \cos\left(\frac{\alpha}{2} + \phi\right) - \frac{\cos(\alpha/2)}{\cos\phi} + \max\left(\tan\phi, 2\sin\frac{\alpha}{2}\sin\phi\right). \end{aligned}$$

For $v \neq 0^+$ the difference between $f(\hat{\theta})$ and $f(\tilde{\theta})$ is even larger and $g(\tilde{\theta})$ does not depend on v , so the value for ε is an upper bound for all v . Combining all the bounds we arrive at the desired result. \square

Note that for $\phi = 0$ this bound reduces to $v^2 \leq -2gR(1 + \sin\theta)$. In other words, this bound is as tight as possible when the surface is horizontal.

For an arbitrary d_n it is not possible to compute the optimal ξ analytically. Fortunately, we *can* analytically solve for ξ if we assume that the bounce consists of pure translation. The resulting ξ can be used as an approximation. It can be shown that the solution for ξ can be written as

$$\cos\xi = \frac{\cos\phi}{\sqrt{2}\sqrt{1-\sin\phi}} \wedge \sin\xi = \frac{\sqrt{1-\sin\phi}}{\sqrt{2}}.$$

Substituting these values in equation 4, we find that the approximation for the bound for Δv^2 then simplifies to

$$\Delta v^2 \leq -\frac{2gd_n}{\cos\phi} + \frac{v^2\sin\phi}{1-\sin\phi}\left(1 + \sqrt{1 - 4d_n g \frac{1-\sin\phi}{v^2\cos\phi}}\right)$$

The relative error in this approximation depends on ϕ , d_n , v and g and can be computed numerically. Somewhat surprisingly, the relative error appears to be constant in v , d_n and g . The relative error does vary significantly with ϕ , but is still fairly small (on the order of 10^{-2}).
